Peter N.  
Robinson

Basics

Review

The process of puzzling together a complete genome sequence of an organism for which shotgun sequencing has been performed is referred to as **genome assembly**.

- As the costs for sequencing have declined, the major challenge becomes computational
- Can we sequence and de novo assemble a large ( $> 100$  Mb) genome with the short (50-250bp) reads typical of current NGS protocols?

# Genome assembly: the basics

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

- There are two major classes of assembly algorithms
  - ① Overlap-layout consensus (OLC)
  - ② De bruijn graph (DBG)
- OLC was widely used back in the day when sequencing was performed by the low-throughput, longer-read Sanger method.
- DBG based methods have dominated the scene since the introduction of NGS

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

To get intuition about genome assembly, let us consider a **idealized genome** that represents a long random sequence of four bases and that does not contain repeats or other complex structures.

- Consider the simplest sequencing strategy: single-end, **whole-genome shotgun** (WGS).
- That is, we sample equal-length fragments with starting points randomly distributed across the genome
- For now, ignore sequencing errors and biases

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

- Thus, our shotgun sequencing can be likened to a process that samples bases from all genome positions at random
- The chance that any particular base is sampled is very low in a single sampling process
- However, we perform the sampling process a very large number of times

Any suggestions as to how we might model this?

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

The Poisson distribution expresses the probability of a given number of events occurring in a fixed interval of time and/or space if these events are iid.

$$f(k; \lambda) = P(X = k) = \frac{e^{-\lambda} \lambda^k}{k!} \quad (1)$$

- $k$  refers to number of reads that overlap a certain genomic position (“coverage”)
- $\lambda$  mean sequencing depth

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

Let's look at the model more closely

- $G$ : genome size (e.g.,  $3.2 \times 10^9$  nucleotides for humans)
- $L$ : read length (e.g., 100 nucleotides for a typical Illumina run)
- $N$ : read number
- $n_b$ : total number of sequenced bases

It is now easy to calculate that

$$n_b = N \times L \quad (2)$$

- Similarly, the average coverage depth per base is  $d_b = \frac{n_b}{G}$

# Sequencing data: Models and intuition

**k-mers:** subsequences with k nucleotides (here: k=3)

- Consider the following k-mers in a small genome of 17 nucleotides

Composition<sub>k</sub>(TCATTC TTCAGGTCAAA)  
TCA  
CAT  
ATT  
TTC  
TCT  
CTT  
TTC  
TCA  
CAG  
AGG  
GGT  
GTC  
TCA  
CAA  
AAA

- How many 3-mers are there in this genome?

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

- In general there are  $L - k + 1$   $k$ -mer subsequences in a sequence of length  $L$  with  $k \leq L$ .
- Let's say we want to know the total number of  $k$ -mers in our WGS data. Since we have  $N$  reads, each of which has  $L - k + 1$   $k$ -mer subsequences, the total number of  $k$ -mers ( $n_k$ ) is

$$n_k = N \times (L - k + 1) \quad (3)$$

- The coverage depth for  $k$ -mers is then  $d_k = \frac{n_k}{G}$ .
- The ratio between the coverage depth for bases and that for  $k$ -mers is then

$$\frac{d_b}{d_k} = \frac{n_b/G}{n_k/G} = \frac{L}{L - k + 1} \quad (4)$$

# Sequencing data: Models and intuition

Say we are performing de novo sequencing for an organism that has not been sequenced before. How can we estimate its overall genome size?

- The number of k-mers in the WGS reads ( $n_k$ ) can be directly counted
- The mean coverage depth of k-mers can be estimated from the peak value of the empirical k-mer coverage depth distribution curve

peak depth value  $d_k = 30.4$

Graphic: Zhenyu Li et al.,  
Briefings in functional genomics  
(2012) 11 (1): 25-37.

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

With this data in hand, we can now estimate the genome size as

$$G \approx \frac{n_k}{d_k} \quad (5)$$

and we can estimate the actual base coverage by

$$d_b \approx \frac{L}{L - k + 1} \times d_k \quad (6)$$

- Here, we would use a value of  $k$  such that we do not expect to see a given  $k$ -mer more than once in a random genome
- In practice, these estimates are not exact even in a random genome because of sequencing errors (why?).

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

Getting back to our initial question, we can now use the mean base coverage estimate  $\lambda = d_b$  to estimate the probability that a given base will not be covered

$$P(X = 0) = \frac{e^{-\lambda} \lambda^0}{0!} = e^{-\lambda} \quad (7)$$

Therefore, the probability of seeing at least one read at a given position is

$$P(X > 0) = 1 - e^{-\lambda} \quad (8)$$

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

- So if we want to estimate the mean read depth required such that at least 99% of the genome is covered once (and thus the probability of any base is at least 99%)<sup>1</sup>, we have

$$\begin{aligned}P(X > 0) = 0.99 &= 1 - e^{-\lambda} \\ e^{-\lambda} &= 0.01 \\ -\lambda &= -4.605\end{aligned}$$

- Thus we need to sequence to an average depth of at least 4.6 to get at least 99% of the genome covered at least once.
- This roughly explains the goal of 6x coverage in initial Sanger sequencing projects of the human genome

---

<sup>1</sup>linearity of expectation

# Sequencing data: Models and intuition

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

Now let us consider **contigs**: combinations of overlapping reads that represent contiguous sequence

- Collection of  $N = 21$  **reads** assembled into 6 **contigs**
- The contigs are assumed to be the best possible representation of the original DNA sequence
- Note that the actual locations of the contigs and their orientation to one another are unknown to us.

# Sequencing data: Models and intuition

Read Mapping (1)

- Key questions: How many contigs are there? How big are the gaps? How long are the contigs?

Overlap between communism and capitalism

# Whole genome shotgun: Contigs and Overlaps

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

Recall our definitions

- $G$ : genome size. Assume  $3 \times 10^9$  nucleotides
- $L$ : read length. Assume 500 nucleotides
- $N$ : read number
- $n_b = N \cdot L$ : total number of sequenced bases
- $\lambda = NL/G$  is the coverage

For instance, 10x coverage of the human genomes requires

$$N = \lambda G/L = 10 \cdot 3 \times 10^9 / 500 = 60 \text{ million reads}$$

# Reads: Probability to start at a given base

## Read Mapping (1)

Peter N.  
Robinson

Basics

Review

- In a genome of length  $G$ , a read of length  $L$  can start anywhere except at the very ends of the chromosomes
- In humans there are  $c = 23$  chromosomes, so  $c \times (L - 1)$  positions cannot represent start positions.
- For  $L = 500$ , we have  $23 \times 499 = 11477$  such positions, but these can be ignored in a genome of  $3 \times 10^9$  nucleotides
- Thus, the probability that a read starts at base  $i$  is well approximated by  $P(\text{read starts at } i) \approx N/G$  if there are a total of  $N$  reads

# Reads: Probability to start in an interval

## Read Mapping (1)

Peter N. Robinson

Basics

Review

- Consider an interval  $I$  that is as long as a read ( $L$  nucleotides).
- The expected number of reads that start in  $I$  is then  $\lambda = L \times N/G$ .
- Assuming a Poisson distribution, the probability that no read starts in  $I$  is then

$$P(X = 0) = \frac{e^{-\lambda} \lambda^0}{0!} = e^{-\lambda} \quad (9)$$

- The probability that at least one read starts in  $I$  is then

$$P(X > 0) = 1 - P(X = 0) = 1 - e^{-\lambda} \quad (10)$$

# Reads: Probability to start in an interval

- Consider a nucleotide at position  $i$
- This nucleotide is in a gap between contigs if no read starts in the interval

$$[i - L + 1, i]$$

- This interval has length  $L$ , and thus, the probability that no read starts in it is  $e^{-\lambda}$
- By linearity of expectation, we can estimate the number of nucleotides in gaps across the entire assembly as

$$G \cdot e^{-\lambda}$$

- Correspondingly, the number of nucleotides included in contigs is  $G \cdot (1 - e^{-\lambda})$

# Contigs: How many are there?

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

- Each contig has a unique rightmost read (“R”)
- The probability that a given read is the rightmost read is the same as the probability that no other read starts within the read
- If the read starts at position  $i$ , this is the probability that no read starts within the interval  $[i - L + 1, i]$ , which we have already calculated as  $e^{-\lambda}$

# Contigs: How many are there?

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

- The number of contigs must be equal to the number of rightmost reads
- There are a total of  $N$  reads, each of which has a probability of  $e^{-\lambda}$  of being an R reads. Thus, the expected number of contigs is

$$Ne^{-\lambda}$$

- The expected number of reads per contig is then  $1/e^{-\lambda}$

# Contigs: How big are they?

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

- We have seen that the expected size of the sequenced region of the genome is  $(1 - e^{-\lambda}) \cdot G$
- The expected number of contigs is  $Ne^{-\lambda}$ . Therefore, the expected size of a contig is simply

$$\frac{(1 - e^{-\lambda}) \cdot G}{Ne^{-\lambda}}$$

- Thus if we go for a coverage of  $\lambda = 6$  of the human genome with 500 nt reads, we would expect roughly
  - 1  $N = \lambda G/L = 36$  million reads
  - 2  $100\% \times (1 - e^{-\lambda}) = 99.8\%$  of the genome being sequenced
  - 3 A total of  $Ne^{-\lambda} = 89,235$  contigs
  - 4 An average contig length of  $\frac{(1 - e^{-\lambda}) \cdot G}{Ne^{-\lambda}} = 33,536$  nucleotides

# Contigs and overlaps

But we have completely neglected the topic of **how much of an overlap** is required to connect two reads?

- Let say we require an overlap of one nucleotide only
- Then any two random reads will overlap with a probability of  $1/4$  – not exactly what we want...
- Let  $\theta$  refer to the proportion of  $L$  required to detect an overlap

- We will now combine a group of reads to a contig if they are connected by overlaps of length  $\geq \theta L$

# Expected number of contigs

Read  
Mapping (1)

Peter N.  
Robinson

Basics

Review

Let us now calculate the expected number of contigs, given that we demand an overlap of at least  $\theta L$  between combined reads

- , As before the probability that a read starts at a given position is  $N/G$
- The probability that  $k$  reads start in an interval that is  $L$  long is again approximated by the Poisson
- The calculation that a given read at position  $i$  is the rightmost read now requires not that there is no read in the interval  $[i - L + 1, i]$ , but instead that there is no read in the leftmost  $(1 - \theta)$  proportion of this interval

# Expected number of contigs

- We need to calculate the probability that zero reads start in  $(1-\theta)L$ .
- Above, the expected number of reads that start in  $l$  of length  $L$  is then  $\lambda = L \times N/G$ .
- Here, we adjust this to reflect the expected number of reads that start in  $(1-\theta)L$  to be  $(1-\theta)\lambda$ .

# Expected number of contigs

## Read Mapping (1)

Peter N. Robinson

Basics

Review

- The expected number of contigs is then  $N$  (number of reads) time the probability that a read is the rightmost read of an island, which is equivalent to their being no reads starting in  $(1 - \theta)L$

$$\begin{aligned}\mathbb{E}[\#\text{contigs}] &= N \times P(\text{no read starts in } (1 - \theta)L) \\ &= Ne^{-(1-\theta)\lambda} \\ &= Ne^{-(1-\theta)LN/G} \quad \blacksquare \quad \text{by definition of } \lambda\end{aligned}$$

Review

A **Eulerian cycle** is a path that traverses every edge exactly once and returns at the end of the traversal to the start node.

- Does this graph contain a Eulerian cycle?

# N50

The N50 measure is used to estimate the quality of a genome assembly

- Arrange the contigs from largest to smallest
- Find the position where the contigs cover 50% of the total genome size
- The length of the contig at this position is defined as the **N50**
- The longer the N50 is, the better the assembly
